**Associative Memory**

**Topics:**

1. **Associative Memory (AM) Description**
   Content addressability: Working of AM: AM Classes: auto and hetero: AM related terms - encoding or memorization, retrieval or recollection, errors and noise: Performance measure - memory capacity and content-addressability.

2. **Associative Memory Models: AM Classes — auto and hetero:** AM Models: Network architectures - Linear associator, Hopfield model and Bi-directional model (BAM).

4. **Bi-directional Hetero-associative Memory (hetero-correlators):** BAM operations - retrieve the nearest pair, Addition and deletion of pattern pairs: Energy function for 5AM - working of Kosko’s BAM, incorrect recall of pattern: Multiple training encoding strategy — augmentation matrix, generalized correlation matrix and algorithm.

**What is Associative Memory?**

- An associative memory is a content-addressable structure that maps a set of input patterns to a set of output patterns.

- A content-addressable structure is a type of memory that allows the recall of data based on the degree of similarity between the input pattern and the patterns stored in memory.

- There are two types of associative memory: auto-associative and hetero-associative.

- An auto-associative memory retrieves a previously stored pattern that most closely resembles the current pattern.

- In a hetero-associative memory, the retrieved pattern is in general, different from the input pattern not only in content but possibly also in type and format.

- Neural networks are used to implement these associative memory models called NAM (Neural associative memory).
An associative memory is a content-addressable structure that maps a set of input patterns to a set of output patterns. A content-addressable structure refers to a memory organization where the memory is accessed by its content as opposed to an explicit address in the traditional computer memory system. The associative memory are of two types: auto-associative and hetero-associative.

- An **auto-associative memory** retrieves a previously stored pattern that most closely resembles the current pattern.

- In **hetero-associative memory**, the retrieved pattern is in general different from the input pattern not only in content but possibly also in type and format.

**Description of Associative Memory**

An associative memory is a content-addressable structure that allows, the recall of data, based on the **degree of similarity** between the input pattern and the patterns stored in memory.

**Example: Associative Memory**

The figure below shows a memory containing names of several people.

If the given memory is content-addressable,

Then using the erroneous string "Crhistpher Columbos" as key is sufficient to retrieve the correct name "Christopher Colombo.

In this sense, this type of memory is robust and fault-tolerant, because this type of memory exhibits some form of **error-correction capability**.
**Fig. A content-addressable memory, Input and Output**

Note: An associative memory is accessed by its content, opposed to an explicit address in the traditional computer memory system. The memory allows the recall of information based on partial knowledge of its contents.

- Associative memory is a system that associates two patterns \((X, Y)\) such that when one is encountered, the other can be recalled. The associative memory are of two types: auto-associative memory and hetero-associative memory.

**Auto-associative memory**
Consider, \(y[1], y[2], y[3], \ldots, y[M]\), be the number of stored pattern vectors and let \(y(m)\) be the components of these vectors, representing features extracted from the patterns. The auto-associative memory will output a pattern vector \(y(m)\) when inputting a noisy or incomplete version of \(y(m)\).

**Hetero-associative memory**
Here the memory function is more general. Consider, we have a number of key-response pairs \(\{c(1), y(1)\}, \{c(2), y(2)\}, \ldots, \{c(M), y(M)\}\). The hetero-associative memory will output a pattern vector \(y(m)\) if a noisy or incomplete version of the \(c(m)\) is given.
Neural networks are used to implement associative memory models. The well-known neural associative memory models are:

- **Linear associater** is the simplest artificial neural associative memory.
- **Hopfield model** and **Bidirectional Associative Memory (BAM)** are the other popular ANN models used as associative memories.

These models follow different neural network architectures to memorize information.

**Example**

An associative memory is a storehouse of associated patterns which are encoded in some form.

- When the storehouse is triggered or excited with a pattern, then the associated pattern pair is recalled or appears at the output.
- The input could be an exact or distorted or partial representation of a stored pattern.

Fig below illustrates the working of an associated memory.

![Fig. Working of an associated memory](image)

When the memory is triggered with an input pattern say Δ then the associated pattern Γ is retrieved automatically.
**Associative Memory - Classes**

As stated before, there are two classes of associative memory:

- auto-associative and
- hetero-associative memory.

An **auto-associative memory**, also known as **auto-associative correlator**, is used to retrieve a previously stored pattern that most closely resembles the current pattern;

A **hetero-associative memory**, also known as **hetero-associative correlator**, is used to retrieve pattern in general, different from the input pattern not only in content but possibly also different in type and format.

**Examples**

![Diagram](image)

- **Hetero-associative memory**
  - Input pattern presented
  - Recall of associated pattern

- **Auto-associative memory**
  - Presented distorted pattern
  - Recall of perfect pattern

*Fig. Hetero and Auto Associative memory Correlators*
Related Terms

Here explained: Encoding or memorization, Retrieval or recollection, Errors and Noise, Memory capacity and Content-addressability.

Encoding or memorization

Building an associative memory means, constructing a connection weight matrix $\mathbf{W}$ such that when an input pattern is presented, and the stored pattern associated with the input pattern is retrieved.

This process of constructing the connection weight matrix is called encoding. During encoding, for an associated pattern pair $(\mathbf{X}_k, \mathbf{Y}_k)$, the weight values of the correlation matrix $\mathbf{W}_k$ are computed as

$$(w_{ij})_k = (x_i)_k (y_j)_k,$$

where

$(x_i)_k$ represents the $i^{th}$ component of pattern $\mathbf{X}_k$, and

$(y_j)_k$ represents the $j^{th}$ component of pattern $\mathbf{Y}_k$

for $i = 1, 2, \ldots, m$ and $j = 1, 2, \ldots, n$.

Constructing of the connection weight matrix $\mathbf{W}$ is accomplished by summing up the individual correlation matrices $\mathbf{W}_k$, i.e.,

$$\mathbf{W} = \alpha \sum_{k=1}^{p} \mathbf{W}_k$$

where

$\alpha$ is the proportionality or normalizing constant.
Retrieval or recollection

After memorization, the process of retrieving a stored pattern, given an input pattern, is called decoding.

Given an input pattern $\mathbf{X}$, the decoding or recollection is accomplished by:

first compute the net input to the output units using

$$\text{input}_j = \sum_{i=1}^{m} x_i w_{ij}$$

where $\text{input}_j$ is weighted sum of the input or activation value of node $j$, for $j = 1, 2, ..., n$.

then determine the units output using a bipolar output function:

$$Y_j = \begin{cases} +1 & \text{if } \text{input}_j \geq \theta_j \\ -1 & \text{otherwise} \end{cases}$$

where $\theta_j$ is the threshold value of output neuron $j$.

Errors and noise

The input pattern may contain errors and noise, or may be an incomplete version of some previously encoded pattern.

When a corrupted input pattern is presented, the network will retrieve the stored pattern that is closest to actual input pattern.

The presence of noise or errors results only in a mere decrease rather than total degradation in the performance of the network.

Thus, associative memories are robust and fault tolerant because of many processing elements performing highly parallel and distributed computations.
**Performance Measures**

The **memory capacity** and **content-addressability** are the measures of associative memory performance for correct retrieval. These two performance measures are related to each other.

**Memory capacity** refers to the maximum number of associated pattern pairs that can be stored and correctly retrieved.

**Content-addressability** is the ability of the network to retrieve the correct stored pattern.

If input patterns are mutually orthogonal - perfect retrieval is possible.

If the stored input patterns are not mutually orthogonal - non-perfect retrieval can happen due to crosstalk among the patterns.

---

**Associative Memory Models**

An associative memory is a system which stores mappings of specific input representations to specific output representations.

- An associative memory "associates" two patterns such that when one is encountered, the other can be reliably recalled.

- Most associative memory implementations are realized as connectionist networks.

The simplest associative memory model is **Linear associator**, which is a feed-forward type of network. It has very low memory capacity and therefore not much used.

The popular models are **Hopfield Model** and **Bi-directional Associative Memory (BAM)** model.

The Network Architecture of these models are presented in this section.
**Associative Memory Models**

The simplest and among the first studied associative memory models is **Linear associator**. It is a feed-forward type of network where the output is produced in a single feed-forward computation. It can be used as an auto-associator as well as a hetero-associator, but it possesses a very low memory capacity and therefore not much used.

The popular associative memory models are **Hopfield Model** and **Bi-directional Associative Memory (BAM) model**.

- The **Hopfield model** is an auto-associative memory, proposed by John Hopfield in 1982. It is an ensemble of simple processing units that have a fairly complex collective computational abilities and behavior. The Hopfield model computes its output recursively in time until the system becomes stable. Hopfield networks are designed using bipolar units and a learning procedure.

- The **Bi-directional associative memory (BAM) model** is similar to linear associator, but the connections are bi-directional and therefore allows forward and backward flow of information between the layers. The BAM model can perform both auto-associative and hetero-associative recall of stored information.
**Network Architectures of AM Models**

The neural associative memory models follow different neural network architectures to memorize information. The network architectures are either single layer or two layers.

- The **Linear associator model**, is a feed forward type network, consists, two layers of processing units, one serving as the input layer while the other as the output layer.

- The **Hopfield model**, is a single layer of processing elements where each unit is connected to every other unit in the network other than itself.

- The **Bi-directional associative memory (BAM) model** is similar to that of linear associator but the connections are bidirectional.

In this section, the neural network architectures of these models and the construction of the corresponding connection weight matrix $\mathbf{W}$ of the associative memory are illustrated.
**Linear Associator Model** (two layers)

It is a feed-forward type network where the output is produced in a single feed-forward computation. The model consists of two layers of processing units, one serving as the input layer while the other as the output layer. The inputs are directly connected to the outputs, via a series of weights. The links carrying weights connect every input to every output. The sum of the products of the weights and the inputs is calculated in each neuron node. The network architecture of the linear associator is as shown below.

![Linear associator model diagram](image)

- all **n** input units are connected to all **m** output units via a weight matrix \( W = [w_{ij}]_{n \times m} \) where \( w_{ij} \) denotes the weight of the unidirectional connection from the \( i \)th input unit to output unit.

- the connection weight matrix stores the **p** different as pattern pairs \( \{(x_k, y_k) \mid k = 1, 2, \ldots, p\} \).

- building an associative memory is constructing the corresponding weight matrix \( W \) such that when an input pattern is presented, then the stored pattern associated with the input pattern is retrieved.
- all $n$ input units are connected to all $m$ output units via connection weight matrix $W = [w_{ij}]_{n \times m}$ where $w_{ij}$ denotes the strength of the unidirectional connection from the $i^{th}$ input unit to the $j^{th}$ output unit.

- the connection weight matrix stores the $p$ different associated pattern pairs $\{(X_k, Y_k) \mid k = 1, 2, ..., p\}$.

- building an associative memory is constructing the connection weight matrix $W$ such that when an input pattern is presented, then the stored pattern associated with the input pattern is retrieved.

- **Encoding**: The process of constructing the connection weight matrix is called encoding. During encoding the weight values of correlation matrix $W_k$ for an associated pattern pair $(X_k, Y_k)$ are computed as:
  
  $$(w_{ij})_k = (x_i)_k (y_j)_k \quad \text{where}$$
  
  $$(x_i)_k \quad \text{is the } i^{th} \quad \text{component of pattern } X_k \quad \text{for } i = 1, 2, ..., m,$$
  
  $$(y_j)_k \quad \text{is the } j^{th} \quad \text{component of pattern } Y_k \quad \text{for } j = 1, 2, ..., n.$$

- **Weight matrix**: Construction of weight matrix $W$ is accomplished by summing those individual correlation matrices $W_k$, i.e., $W = \alpha \sum_{k=1}^{p} W_k$ where $\alpha$ is the constant of proportionality, for normalizing, usually set to $1/p$ to store $p$ different associated pattern pairs.

- **Decoding**: After memorization, the network can be used for retrieval; the process of retrieving a stored pattern, is called decoding; given an input pattern $X$, the decoding or retrieving is accomplished by computing, first the net Input as $\text{input } j = \sum_{j=1}^{m} x_i \ w_{ij}$ where $\text{input } j$ stands for the weighted sum of the input or activation value of node $j$, for $j = 1, 2, ..., n$. and $x_i$ is the $i^{th}$ component of pattern $X_k$, and then determine the units Output using a bipolar output function:
  
  $$Y_j = \begin{cases} 
  +1 & \text{if } \text{input } j \geq \theta_j \\
  -1 & \text{otherwise} 
  \end{cases}$$

  where $\theta_j$ is the threshold value of output neuron $j$.

  Note: The output units behave like linear threshold units; that compute
a weighted sum of the input and produces a $-1$ or $+1$ depending whether the weighted sum is below or above a certain threshold value.

- **Performance**: The input pattern may contain errors and noise, or an incomplete version of some previously encoded pattern. When such corrupt input pattern is presented, the network will retrieve the stored pattern that is closest to actual input pattern. Therefore, the linear associator is **robust and fault tolerant**. The presence of noise or error results in a mere decrease rather than total degradation in the performance of the network.

**Auto-associative Memory Model - Hopfield model** (single layer)

Auto-associative memory means patterns rather than associated pattern pairs, are stored in memory. Hopfield model is one-layer unidirectional auto-associative memory.

![Hopfield network](image)

**Fig. Hopfield model with four units**
- the model consists, a single layer of processing elements where each unit is connected to every other unit in the network but not to itself.
- connection weight between or from neuron \( j \) to \( i \) is given by a number \( w_{ij} \). The collection of all such numbers are represented by the weight matrix \( W \) which is square and symmetric, ie, \( w_{ij} = w_{ji} \) for \( i, j = 1, 2, \ldots, m \).
- each unit has an external input \( I \) which leads to a modification in the computation of the net input to the units as

\[
\text{input}_j = \sum_{i=1}^{m} x_i w_{ij} + I_j \quad \text{for} \quad j = 1, 2, \ldots, m.
\]

and \( x_i \) is the \( i^{th} \) component of pattern \( X_k \)

- each unit acts as both input and output unit. Like linear associator, a single associated pattern pair is stored by computing the weight matrix as \( W_k = X_k^T Y_k \) where \( X_k = Y_k \)
- **Weight Matrix**: Construction of weight matrix $W$ is accomplished by summing those individual correlation matrices, i.e., $W = \alpha \sum_{k=1}^{p} W_k$ where $\alpha$ is the constant of proportionality, for normalizing, usually set to $1/p$ to store $p$ different associated pattern pairs. Since the Hopfield model is an auto-associative memory model, it is the patterns rather than associated pattern pairs, are stored in memory.

- **Decoding**: After memorization, the network can be used for retrieval; the process of retrieving a stored pattern, is called decoding; given an input pattern $X$, the decoding or retrieving is accomplished by computing, first the net Input as $\text{input}_j = \sum_{j=1}^{m} x_i w_{ij}$ where $\text{input}_j$ stands for the weighted sum of the input or activation value of node $j$, for $j = 1, 2, \ldots, n.$ and $x_i$ is the $i^{th}$ component of pattern $X_i$, and then determine the units Output using a bipolar output function:

$$Y_j = \begin{cases} +1 & \text{if } \text{input}_j \geq \theta_j \\ -1 & \text{otherwise} \end{cases}$$

where $\theta_j$ is the threshold value of output neuron $j$.

Note: The output units behave like linear threshold units; that compute a weighted sum of the input and produces a $-1$ or $+1$ depending whether the weighted sum is below or above a certain threshold value.

Decoding in the Hopfield model is achieved by a collective and recursive relaxation search for a stored pattern given an initial stimulus pattern. Given an input pattern $X$, decoding is accomplished by computing the net input to the units and determining the output of those units using the output function to produce the pattern $X'$. The pattern $X'$ is then fed back to the units as an input pattern to produce the pattern $X''$. The pattern $X''$ is again fed back to the units to produce the pattern $X'''$. The process is repeated until the network stabilizes on a stored pattern where further computations do not change the output of the units.

In the next section, the working of an auto-correlator: how to store patterns, recall a pattern from the stored patterns and how to recognize a noisy pattern are explained.
**Bidirectional Associative Memory** (two-layer)

Kosko (1988) extended the Hopfield model, which is single layer, by incorporating an additional layer to perform recurrent auto-associations as well as hetero-associations on the stored memories. The network structure of the bidirectional associative memory model is similar to that of the linear associator but the connections are bidirectional; i.e.,

$$w_{ij} = w_{ji}, \text{ for } i = 1, 2, \ldots, n \text{ and } j = 1, 2, \ldots, m.$$  

![Bidirectional Associative Memory model](image)

- In the bidirectional associative memory, a single associated pattern pair is stored by computing the weight matrix as $W_k = X_k^T f_k$.

- The construction of the connection weight matrix $W$, to store $p$ different associated pattern pairs simultaneously, is accomplished by summing up the individual correlation matrices $W_k$, i.e.,

$$W = \alpha \sum_{k=1}^{p} W_k$$

where $\alpha$ is the proportionality or normalizing constant.
Auto Associative Memory (auto-correlators)

In the previous section, the structure of the Hopfield model has been explained. It is an auto-associative memory model which means patterns, rather than associated pattern pairs, are stored in memory. In this section, the working of an auto-associative memory (auto-correlator) is illustrated using some examples.

Working of an auto-correlator:

- how to store the patterns,
- how to retrieve / recall a pattern from the stored patterns, and
- how to recognize a noisy pattern

How to Store Patterns: Example

Consider the three bipolar patterns $A_1$, $A_2$, $A_3$ to be stored as an auto-correlator.

$A_1 = (-1, 1, -1, 1)$
$A_2 = (1, 1, -1, -1)$
$A_3 = (-1, -1, -1, 1)$

Note that the outer product of two vectors $U$ and $V$ is

$$U \otimes V = U^T V = \begin{pmatrix} U_1 \\ U_2 \\ U_3 \\ U_4 \end{pmatrix} \begin{pmatrix} V_1 \\ V_2 \\ V_3 \end{pmatrix} = \begin{pmatrix} U_1 V_1 & U_1 V_2 & U_1 V_3 \\ U_2 V_1 & U_2 V_2 & U_2 V_3 \\ U_3 V_1 & U_3 V_2 & U_3 V_3 \\ U_4 V_1 & U_4 V_2 & U_4 V_3 \end{pmatrix}$$

Thus, the outer products of each of these three $A_1$, $A_2$, $A_3$ bipolar patterns are

$$a_{i,j} = \begin{pmatrix} 1 & -1 & 1 & -1 \\ -1 & 1 & -1 & 1 \\ 1 & -1 & 1 & -1 \\ -1 & 1 & -1 & 1 \end{pmatrix}$$
\[
\begin{align*}
T^{T} \\
\begin{bmatrix} [A_{2}]_{4 \times 1} & [A_{2}]_{1 \times 4} \end{bmatrix} &= \begin{bmatrix}
1 & 1 & 1 & -1 \\
1 & 1 & 1 & -1 \\
1 & 1 & 1 & -1 \\
-1 & -1 & -1 & 1
\end{bmatrix} \\
& \downarrow \\
& \begin{bmatrix} i \rightarrow j \end{bmatrix}
\end{align*}
\]

\[
\begin{align*}
T^{T} \\
\begin{bmatrix} [A_{3}]_{4 \times 1} & [A_{3}]_{1 \times 4} \end{bmatrix} &= \begin{bmatrix}
1 & 1 & 1 & -1 \\
1 & 1 & 1 & -1 \\
1 & 1 & 1 & -1 \\
-1 & -1 & -1 & 1
\end{bmatrix} \\
& \downarrow \\
& \begin{bmatrix} i \rightarrow j \end{bmatrix}
\end{align*}
\]

Therefore the connection matrix is

\[
T = [t_{ij}] = \sum_{i=1}^{3} [A_{i}]_{4 \times 1}^{T} [A_{i}]_{1 \times 4} = \begin{bmatrix}
3 & 1 & 3 & -3 \\
1 & 3 & 1 & -1 \\
3 & 1 & 3 & -3 \\
-3 & -1 & -3 & 3
\end{bmatrix} \\
& \downarrow \\
& \begin{bmatrix} i \rightarrow j \end{bmatrix}
\]

This is how the patterns are stored.

**Retrieve a Pattern from the Stored Patterns**

The previous slide shows the connection matrix \( T \) of the three bipolar patterns \( A_{1}, A_{2}, A_{3} \) stored as

\[
T = [t_{ij}] = \sum_{i=1}^{3} [A_{i}]_{4 \times 1}^{T} [A_{i}]_{1 \times 4} = \begin{bmatrix}
3 & 1 & 3 & -3 \\
1 & 3 & 1 & -1 \\
3 & 1 & 3 & -3 \\
-3 & -1 & -3 & 3
\end{bmatrix} \\
& \downarrow \\
& \begin{bmatrix} i \rightarrow j \end{bmatrix}
\]

and one of the three stored pattern is \( A_{2} = (1, 1, 1, -1) \)

- Retrieve or recall of this pattern \( A_{2} \) from the three stored patterns.
- The recall equation is

\[
a_{i}^{new} = f(a_{i}^{old}, t_{ij}) \] for \( \forall j = 1, 2, \ldots, p \)

Computation for the recall equation \( A_{2} \) yields

\[
\begin{align*}
\alpha &= \sum a_{i} t_{i,j} \\
\alpha &= \sum a_{i} t_{i,j} \\
\alpha &= \sum a_{i} t_{i,j} \\
\alpha &= \sum a_{i} t_{i,j}
\end{align*}
\]

\[
\begin{align*}
\begin{array}{cccccc}
i = 1 & 2 & 3 & 4 & \alpha & \beta \\
1x3 & + & 1x1 & + & 1x3 & + & -1x-3 \\
1x1 & + & 1x3 & + & 1x1 & + & -1x-1 \\
1x3 & + & 1x1 & + & 1x3 & + & -1x-3 \\
1x-3 & + & 1x-1 & + & 1x-3 & + & -1x3 \\
\end{array}
\end{align*}
\]

\[
\begin{align*}
\begin{array}{cccc}
& 1 & 2 & 3 & 4 \end{array} & \begin{array}{c}
\alpha \beta \\
10 & 1 \\
6 & 1 \\
10 & 1 \\
-1 & -1
\end{array}
\end{align*}
\]
Therefore $a_{j}^{\text{new}} = f(a_{i}^{\text{old}}, a_{j}^{\text{old}})$ for $v_{j} = 1, 2, \ldots, p$ is $f(\alpha, \beta)$

\[
\begin{align*}
    a_{1}^{\text{new}} &= f(10, 1) \\
    a_{2}^{\text{new}} &= f(6, 1) \\
    a_{3}^{\text{new}} &= f(10, 1) \\
    a_{4}^{\text{new}} &= f(-1, -1)
\end{align*}
\]

The values of $\beta$ is the vector pattern $(1, 1, 1, -1)$ which is $A_{2}$.

This is how to retrieve or recall a pattern from the stored patterns.

Similarly, retrieval of vector pattern $A_{3}$ as

\[
( a_{1}^{\text{new}}, a_{2}^{\text{new}}, a_{3}^{\text{new}}, a_{4}^{\text{new}} ) = (-1, -1, -1, 1) = A_{3}
\]

**Recognition of Noisy Patterns**

Consider a vector $A' = (1, 1, 1, 1)$ which is a noisy presentation of one among the stored patterns.

- find the proximity of the noisy vector to the stored patterns using Hamming distance measure.
- note that the Hamming distance (HD) of a vector $X$ from $Y$, where $X = (x_{1}, x_{2}, \ldots, x_{n})$ and $Y = (y_{1}, y_{2}, \ldots, y_{n})$ is given by

\[
\text{HD}(x, y) = \sum_{i=1}^{m} |(x_{i} - y_{i})|
\]

The HDs of $A'$ from each of the stored patterns $A_{1}, A_{2}, A_{3}$ are

\[
\begin{align*}
    \text{HD}(A', A_{1}) &= \sum |(x_{1} - y_{1})|, |(x_{2} - y_{2})|, |(x_{3} - y_{3})|, |(x_{4} - y_{4})| \\
    &= \sum |(1 - (-1))|, |(1 - 1)|, |(1 - (-1))|, |(1 - 1)| \\
    &= 4 \\
    \text{HD}(A', A_{2}) &= 2 \\
    \text{HD}(A', A_{3}) &= 6
\end{align*}
\]

Therefore the vector $A'$ is closest to $A_{2}$ and so resembles it.

In other words the vector $A'$ is a noisy version of vector $A_{2}$.

Computation of recall equation using vector $A'$ yields:
\[ \alpha = \sum_{i,j} a_{i,j} \]
\[ \alpha = \sum_{i,j} t_{i,j} \]
\[ \alpha = \sum_{i,j} t_{i,j} \]
\[ \alpha = \sum_{i,j} t_{i,j} \]
\[ \alpha = \sum_{i,j} t_{i,j} \]

\[ 1x3 + 1x1 + 1x3 + 1x3 = 4 \]
\[ 1x1 + 1x3 + 1x1 + 1x1 = 4 \]
\[ 1x3 + 1x1 + 1x3 + 1x3 = 4 \]
\[ 1x1 + 1x1 - 1 + 1x3 + 1x3 = -4 \]

Therefore
\[ a_j^{\text{new}} = f(a_{i,j}, a_j^{\text{old}}) \]
for \( j = 1, 2, \ldots, p \) is \( f(\alpha, \beta) \)

\[ a_1^{\text{new}} = f(4, 1) \]
\[ a_2^{\text{new}} = f(4, 1) \]
\[ a_3^{\text{new}} = f(4, 1) \]
\[ a_4^{\text{new}} = f(-4, -1) \]

The values of \( \beta \) is the vector pattern \( (1, 1, 1, -1) \) which is \( A_2 \).

Note: In presence of noise or in case of partial representation of vectors, an autocorrelator results in the refinement of the pattern or removal of noise to retrieve the closest matching stored pattern.

**Bidirectional Hetro-associative Memory**

The Hopfield one-layer unidirectional auto-associators have been discussed in previous section. Kosko (1987) extended this network to two-layer bidirectional structure called Bidirectional Associative Memory (BAM) which can achieve hetero-association. The important performance attributes of the BAM is its ability to recall stored pairs particularly in the presence of noise.

Definition: If the associated pattern pairs \((X, Y)\) are different and if the model recalls a pattern \(Y\) given a pattern \(X\) or vice-versa, then it is termed as hetero-associative memory.

This section illustrates the bidirectional associative memory:
- Operations (retrieval, addition and deletion),
- Energy Function (Kosko's correlation matrix, incorrect recall of pattern),
- Multiple training encoding strategy (Wang's generalized correlation matrix).
Bidirectional Associative Memory (BAM) Operations

BAM is a two-layer nonlinear neural network. Denote one layer as field $A$ with elements $A_i$ and the other layer as field $B$ with elements $B_i$.

The basic coding procedure of the discrete BAM is as follows. Consider $N$ training pairs $\{(A_1, B_1), (A_2, B_2), \ldots, (A_i, B_i), \ldots (A_N, B_N)\}$ where $A_i = (a_{i1}, a_{i2}, \ldots, a_{in})$ and $B_i = (b_{i1}, b_{i2}, \ldots, b_{ip})$ and $a_{ij}, b_{ij}$ are either in ON or OFF state.

- in binary mode, ON = 1 and OFF = 0 and
- in bipolar mode, ON = 1 and OFF = -1

- the original correlation matrix of the BAM is $M_0 = \sum_{i=1}^{N} [X_i^T \ Y_i]$ where $X_i = (x_{i1}, x_{i2}, \ldots, x_{in})$ and $Y_i = (y_{i1}, y_{i2}, \ldots, y_{ip})$

and $x_{ij}(y_{ij})$ is the bipolar form of $a_{ij}(b_{ij})$

The energy function $E$ for the pair $(\alpha, \beta)$ and correlation matrix $M$ is $E = -\alpha M \beta^T$

With this background, the decoding processes, means the operations to retrieve nearest pattern pairs, and the addition and deletion of the pattern pairs are illustrated in the next few slides.
